ABSTRACT

While Global Navigation Satellite System (GNSS) technology has become omnipresent in consumer, automotive, and industrial applications, the adoption of high precision GNSS technology continues to be inaccessible to the mass market due to the lack of a global, dense and optimally distributed GNSS infrastructure network facilitating improvements of positioning to the sub-centimeter level. Such a network would represent the basis to serve an existing market of $\notin 6.7B$ and facilitate novel applications benefiting humanity such as early tsunami warning systems, crustal deformation monitoring and space weather monitoring, on a more larger and more accurate scale than previously possible.

onocoy incentivizes the transparent construction of such a network in a decentralized way with blockchain-based tokens, open standards and hardware, and participatory governance that includes all stakeholders of the ecosystem including existing competing actors and users of their services. In this way, a collectively-owned, community-powered and decentralized GNSS infrastructure as a commons is created that benefits everyone by fostering accessibility, collaboration, and innovation.

Keywords GNSS · Blockchain · DePIN · RTK · web3

1 Introduction

Global Navigation Satellite System (GNSS) technologies use satellite constellations, orbiting Earth, to provide position, navigation, and timing (PNT) information to users on the Earth's surface and in its immediate vicinity. GNSS enables users to determine their location, velocity, and time by the trilateration of signals from multiple satellites. The first and most well-known GNSS is the Global Positioning System (GPS), developed and operated by the United States. Other constellations include the Russian GLONASS, Chinese BeiDou, and European Galileo; besides these, there are some regional navigation satellite systems such as the Japanese QZSS and the Indian NavIC, designed to provide improved PNT over their respective regions.

GNSS has a wide range of applications which are growing beyond its use in positioning and navigation for users at the Earth's surface, which is well-understood by retail consumers, it is also used in determining the position of both aircraft and spacecraft. The use of GNSS is fundamental for determining geolocation in critical situations such as emergency and disaster responses, and search-and-rescue operations, where other methods of positioning can be inadequate: GNSS is necessary when trying to achieve highly accurate, real-time positioning. The importance of its use in timing is

Figure 1: A geographically close GNSS reference receiver is fundamental to improve the positioning accuracy of a rover receiver from a meter to a (sub)centimeter accuracy.

less recognized by the general public. GNSS is important in determining precise times for financial transactions and telecommunications, and synchronization of scientific experiments and network infrastructure. In its relatively short history, GNSS has become an essential technology in many aspects of modern life.

The following paragraph introduces the different approaches used, and performances achievable, when providing positioning services using GNSS. Single Point Positioning (SPP) is the basic positioning principle used with GNSS. It estimates the user's coordinates and clock error through a trilateration of the satellites' position and signal. At meter-level accuracy, the precision of SPP is good enough for many use-cases, but it is limited; various sources of error, such as satellite orbit errors, atmospheric effects, and multipath, i.e. the appearance of multiple signals caused by reflection off surfaces, all contribute to deterioration of precision [Teunissen and Montenbruck, 2017]. For applications that require higher accuracy and precision, High-Precision Positioning techniques like Real-Time Kinematic (RTK) corrections and Precise Point Positioning (PPP) are required. These systems are capable of achieving centimeter to millimeter-level positioning accuracy by primarily mitigating atmospheric effects and resolving carrier-phase ambiguities. Applications of high-precision GNSS is also used in monitoring of the Earth's vibrations and movements, allowing for the measurement of the movement of tectonic plates, monitoring of the melting of glaciers, and development of early tsunami and earthquake warning systems.

While some of the benefits above can be realized with the use of either RTK or PPP, only RTK is able to deliver instantaneous centimeter-level positioning in real-time. The convergence time to centimeter-level accuracy with PPP is primarily due to the estimation of the residual atmospheric errors, which typically takes tens of minutes. RTK, however, relies on a ground-based Continuously Operated Reference Station (CORS) that provides the observed GNSS measurements. Assuming the CORS is within 20km by differencing the measurements between the rover and CORS, all major error sources are eliminated, in contrast to PPP where the unmodelled errors are mitigated through estimation. RTK enables high-precision positioning for objects in motion, as shown in Fig. 1.

With the benefits of RTK having been made clear, what prevents its global realization is a combination of factors: high costs, redundancies, and proprietary standards all play a role. While one may install a CORS to cover an area of interest, the coverage will be limited to a local area. The alternative is then to build a network of reference stations, but the conventional build-out of such a network results in high investment and maintenance costs and gaps in coverage, since central entities focus on only the most profitable areas of coverage. The result is a patchwork of networks and disorganized single-station owners: increased costs, and redundant and patchy coverage. The desired solution is one in which the local model can be scaled globally, so that coverage can be delivered to any region where it might be economical and redundancies may be limited to the amount needed for robustness. Such a network would result in lowered costs and increased performance.

We at onocoy have created the solution to these problems described above by implementing a GNSS reference station infrastructure that is community-owned, decentralized, and efficient. The enabling technologies are those of web3, which is a collection of technologies that incorporate the World Wide Web, distributed ledger technologies, and tokenized economics to enable new kinds of decentralized economies. In particular, ours is a decentralized physical infrastructure (DePIN) project¹, i.e., a web3 project aimed at networked physical infrastructure.

In the onocoy network, any operator of a CORS is able to stream its correction data to the onocoy platform in exchange for tokens. These tokens may be exchanged for data credits, the only method of payment that the onocoy platform accepts for providing the data streams that it collects from reference station operators. The token is therefore a form of equity, tied to the economic value of its data, that empowers its holders, and reference station operators in particular, to behave as owners and stewards of the onocoy network. The incentive to nurture and grow the network extends beyond the potential for price appreciation. The onocoy token unlocks membership in the onocoy association, a Decentralized Autonomous Organization² (DAO) tasked with shepherding the network. With as little as one token, one is able to vote on matters of consequence to the network and shape the destiny of high-precision GNSS. The onocoy network is therefore set up to harness the collective intelligence of all token holders, allowing the calibration of complex system configurations, none of which could be effectively done by a single entity.

Beyond using tokens, the onocoy network implements other tools that continue to enable decentralization, the most important being open standards; onocoy does not require proprietary standards. RTK technology has existed for decades and has an established practice around its use. onocoy has taken a conscious step to support the existing RTK infrastructure so that we may complement the existing ecosystem. With this comes a challenge: since standards are open, one has to differentiate between real and fake data; since the network monetarily incentivizes data collection, there is an incentive for prevarication of data. This implies that the network must check the validity of incoming data before determining a reward. Fortunately, such checks are possible due to the physical nature of the data; there are multiple techniques to verify GNSS data, relying on detecting anomalies within data streams that deviate from our understanding of physics and statistical behavior. In a sense, the onocoy validation scheme provides a non-cryptographic likelihood estimate of physical work having been done. Compared to other projects in web3, this is quite novel, as most web3 projects focus on definitive cryptographic proofs, such as those obtained in Bitcoin's proof-of-work scheme. Since onocoy relies on open standards, and cryptographic protocols are not standard within GNSS, this is not possible to implement.

Nevertheless, what is possible is the implementation of all mechanisms described above, i.e., token awards, voting, and data validation, as decentralized schemes. In the onocoy network, tokens are held within users' wallets, i.e., they are associated with a public cryptographic key whose private keypair is held by an individual user and not accessible by the network. Voting is done on the blockchain, with users using their private key to verify the signature behind a desired vote. Validation is done by decentralized validators; these are validation schemes implemented in combination with smart contracts, or code running on the blockchain, so that the network may provide trust in its functioning.

The current status of onocoy is an early rewarding rollout on the Solana blockchain mainnet. In the early rewarding, reference station owners earn test tokens that may or may not be converted to the actual token at launch. Data is provided to customers free of charge for the duration of the early rewarding, and core aspects of the DAO, such as on-chain voting and decentralization of validators remain off-chain.

The rest of the white paper is structured as follows: onocoy's unique positioning in the GNSS market is illustrated in Section 2. The cryptoeconomic design facilitating an efficient and resilient co-operation of stakeholders within the onocoy network is then given in Section 3. This is followed by introducing onocoy's IT architecture and its approach to validating the correctness of GNSS measurement streams in Section 4. Finally, a summary and call for action is given in Section 5.

2 onocoy's unique positioning – a GNSS market perspective

In this section, we show how onocoy has positioned itself to create and leverage synergies within the GNSS ecosystem. In Section 2.1, we present the existing GNSS market and its challenges with regards to creating a global and dense network of CORSs. In Section 2.2, we then illustrate how onocoy overcomes these challenges with its unique positioning as a community-owned and shared infrastructure. In Section 2.3, we conclude how this ultimately enables novel applications in the service of humanity.

¹For an overview of decentralized physical infrastructure networks (DePINs), see Kassab [2023].

²For an introduction to Decentralized Autonomous Organizations (DAOs), see Merkle [2016].

2.1 Existing GNSS market and its challenges

The biggest markets for real-time high-precision are currently those of machine control, agriculture and logistics. Growth is driven primarily by automation and autonomous vehicles, e.g., last-mile geofenced transportation/delivery services, and is expected to result in a total available GNSS market of \notin 43B in 2028 with a 7% CAGR [EUSPA, 2022]. The market is served by about 20 companies; these are correction service providers that operate CORS, compute correction data, process the data and provide highly-precise positioning to their customers. For this, they rely on a subscription-based business model, charging between \$200 and \$50,000 per year per device. Besides these commercially operating reference station networks, there are free and open networks such as those operated by universities or governments, typically providing coarser coverage and lower-quality data.

The high costs associated with building and maintaining dense CORS networks have limited their adoption to regions with a sufficiently large and affluent customer base – predominantly dense urban areas and regions with highly automated, large-scale agriculture. Markets outside of these regions, particularly in emerging and developing countries, continue to be under-served and, as such, there does not exist a global, high-density CORS network. Moreover, in regions where sufficient network infrastructure exists to the point of redundancy, the redundancy is not leveraged to the benefit of providers, such as providing backup if one station goes down, and thus does not increase the resilience of the infrastructure.

CORS networks need to be regularly updated with new hardware as new signals and constellations become available but much of existing infrastructure gets outdated due to the investments required. Typically, network growth is slowed down because building up a dense global service is costly. Simultaneously, revenues are only realized once it is fully deployed, making it difficult for service operators to roll out dense networks quickly and globally.

Even where sufficient coverage and quality is available, infrastructure is often inadequately exploited. Commercial reference station networks rely on proprietary solutions and communication protocols, restricting their use to specific niches and limiting interoperability across vendors. Due to this fragmentation in this segment, the the number of customers served is limited, hence service costs of each vendor remains high.

For instance, correction service providers utilize business models made for high-end niche markets (e.g., oil tankers) and typically do not pursue a fit with mass markets (e.g., autos): Correction services are often bundled with receivers (see Figure 3), making it hard for users to select the best receiver and the optimal service for their application. It also creates an undesired lock-in with vendors' offerings. Additionally, providers often impose use-case limitations on their customers. This regionally-fragmented correction service landscape makes selling products globally a challenge for hardware producers (OEMs as well as tier 1 and 2) and service operators.

As a result, GNSS correction service costs have not fallen at the same rate as the cost of the required hardware. This impacts the entire industry, with limited adoption of high precision GNSS technology in many mass market applications holding back sales and depriving end-users and entire economies and regions of the technology's benefits.

2.2 onocoys unique positioning – benefiting all stakeholders

To overcome the challenges described above, onocoy positions itself as a three-sided platform (Figure 2) following Gomes Jr. [2022] between station operators, data users (clients), and data validation and provisioning. Using open standards and protocols (i.e. NTRIP RTCM3 MSM), data is received from reference stations and relayed to users via decentralized validators that continuously monitor reference station data quality and alert station operators in the event of performance degradation.

To make the existing and competing industry come together, the platform enables a) collective governance by all of its stakeholders including users and station operators, and prevents b) power concentrations by any one group of stakeholders (see Section 3.5 for details).

This approach affords the strategic positioning of onocoy in the existing GNSS industry as a shared infrastructure commons, complementing and bringing together existing GNSS market stakeholders and new joiners (e.g. crypto miners who want to operate reference stations), and providing synergies and benefits for all (see Figure 4).

By separating the operation of reference stations from the provision of value-added correction services, reference stations can be shared among service providers via open communication protocols and hardware, avoiding redundancies in the reference station infrastructure except those desired for robustness. By engaging communities to set up and manage reference stations and validators, investments and operational costs for a network can be spread over a large number of people, enabling the creation of a global and dense network, as in the case of the Helium network [Jagtap et al., 2021].

Figure 2: onocoy's three-sided market that enables users to receive validated reference data from station operators

Figure 3: Service providers are vertically integrated, resulting in high reference station infrastructure costs.

OEMs

Figure 4: onocoy's strategic positioning in the existing GNSS market as a shared infrastructure benefiting all stakeholders.

onocoy provides publicly accessible, pay-per-use, single-base RTK streams, thereby opening correction data up to mass markets and removing lock-in effects. In particular, by focusing on single-base RTK, onocoy is not in competition with existing correction service providers that focus on value-added service on top of their streams (e.g., VRS, PPP, PPP-RTK; see Section 4.1 for details on these technologies). In fact, onocoy reduces both the capital and operating expenses for these stakeholders and provides an opportunity for them to grow into regions currently not covered by their services, such as Africa, South America, and Asia. Furthermore, these stakeholders can contribute their existing installed base of reference stations to onocoy and gain additional revenue.

Thus, business models suitable for mass-market applications become possible as there is a straight-forward per-use charge and no limitations on market segments are imposed.

In summary, the advantages across the value chain are evident. They are:

- *Reference station operators* gain new, or additional, distribution channels. Throughout a station's lifetime, they may sell data to onocoy for rewards, with upside potential based on data usage in the proximity of their station (see onocoy's rewarding concept in Section 3.3). Moreover, they benefit from real-time data quality monitoring and reporting, guaranteed by onocoy validators.
- *Providers of value-added correction services* profit from cost-effective coverage expansion and additional revenues from their existing network. Instead of needing to make vast infrastructure investments, they utilize onocoy's network and gain access to high-quality stations worldwide, taking advantage of a risk-free path to network expansion and economies of scale.
- *Product manufacturers* benefit from a larger addressable market. Worldwide availability of affordable reference station data and correction services allows for mass adoption and hence increased hardware sales. Furthermore, onocoy's global coverage gives ease-of-use in scaling products and services.
- *System integrators and operators* can expand into new applications and services, with correction data becoming affordable and available everywhere, be it single-base RTK or added value correction services.
- As a result of all of the above, *consumers* gain access to improved and/or new products, applications and services.

onocoy's strategic positioning results in a value proposition that complements existing value-added services in the GNSS industry such that a mass market for high-precision positioning can be formed, built on a global, shared and common CORS infrastructure.

2.3 onocoy enables fair access to novel humanity-serving applications

The creation of a global and dense CORS network will provide cost-effective access to the technology's benefits and enable novel humanity-serving applications: Currently, as illustrated, correction services are only available in high income areas, e.g., Europe and North America, and in niche markets, e.g., precision agriculture, at high cost, thus preventing a large part of the global population from accessing the benefits of applications built on it, e.g., autonomous navigation in South America.

Worse, these barriers prevent the emergence of novel, humanity-serving applications facilitated by a global and dense network such as i) improved weather monitoring and forecasting, ii) long-term climate measurement Guerova and Simeonov [2021], and iii) large scale tsunami warning systems Blewitt et al. [2009] that would be of great value to large parts of the world population by, amongst others, mitigating and addressing the risks of climate change. For instance, I) the ability to monitor weather more effectively and II) long-term climate measurements will improve humanity's ability to assess climate change mitigation actions by providing real-time feedback on countermeasures (required for a complex system such as our society to self-organize Ballandies [2023]), resulting in accelerated learning cycles.

3 onocoy's cryptoeconomic design – efficient and resilient co-operation via web3

The design of the onocoy cryptoeconomy follows a value-sensitive design science research methodology [Ballandies et al., 2022]. This is a principled method that considers stakeholder values explicitly during the design and construction of IT systems [Friedman et al., 2013, Van den Hoven et al., 2015]. Since a lack of consideration of stakeholder values in the construction of a software artifact can result in technology rejection [Helbing, 2021], the failure of including the values of onocoy's stakeholders could prevent its mission of creating a community-powered global RTK reference station network. Therefore it is important to identify the values for the onocoy network. The four most important ones are:

- Participation: The team, investors, and community members must all participate in the project's governance
- Progressive decentralization: The platform's elements must become distributed over the long run
- *Economic sustainability*: onocoy must be a non-profit organization that generates sufficient funds to achieve its mission
- Value sharing: Investors and contributors must have an attractive return/reward

These values are secured via web3 in onocoy's platform by using i) *blockchain-based tokens* for interest realignment among all stakeholders and to crowdsource investment cost into the global and dense reference station network; ii) *DAO*³ *mechanisms* to collectively control, parameterize and govern the complex network; iii) *smart contracts* to instantiate

³Decentralized autonomous organization

Figure 5: A presentation of the main elements of onocoy's cryptoeconomic design, utilizing the conceptual architecture introduced by Ballandies et al. [2021]

cost-effective and transparent mechanisms to handle large amount of micro-transactions in a pay-per-use business model covering all world regions; and iv) a *decentralized distributed ledger* to secure and robustify the network.

Utilizing the conceptual architecture introduced by Ballandies et al. [2021], the main parts of the onocoy system are illustrated in Figure 5. These parts are the i) core economy, ii) off-chain governance, iii) investors, iv) on-chain governance, v) on-chain economy, and v) tokens. In particular, onocoy is a 2nd layer (L2) system built on top of an established blockchain, utilizing smart-contract capability to facilitate on-chain governance and token issuance and transfer. onocoy is therefore a decentralized application (dApp) built on a blockchain maintained by a third-party (community) which is utilized for data storage and computation; this effectively removes the complexity and cost of maintaining one's own blockchain while increasing the transparency and trustworthiness of code/ mechanisms utilized.

At system initialization, some actions reside off-chain, i.e., are not stored within/ executed by the blockchain. These include, in particular, the management of funds received by early investors and the steering of system development. Nevertheless, by following the value of progressive decentralization, onocoy commits itself to over time move as much as reasonably possible on-chain to increase the transparency and trustworthiness of the platform. The core economy that relies on both system tokens is the sharing of GNSS measurements by continuously operating reference stations (CORS), also referred to as miners in web3, with system users.

In this section, we detail the onocoy cryptoeconomic design (CED). In Section 3.1, we describe the token flows. In Section 3.2, we describe the token design. In Section 3.4, we describe the tokenomics. In Section 3.3, we describe the rewarding concepts. In Section 3.5, we describe the governance.

3.1 Token flow and core economy

Figure 6 illustrates the onocoy token model: a *deflationary* burn-and-mint token model that implements an oracle mechanism to ensure stable FIAT prices for customers that the GNSS industry is accustomed to, while allowing for strong token appreciation [Kalabić et al., 2023], important for the success of a blockchain project. This is achieved by ensuring stable FIAT prices for data access with the non-transferable data credit, while leveraging the advantages of cryptoeconomic tokens for governance and incentives via the freely-tradeable ONO token. The ONO token is a utility token that can appreciate in value and is traded at exchanges and contributors to the project are rewarded with ONO tokens. The ONO token also gives access to onocoy's governance. Moreover, ONO tokens can be swapped into data credits through a system-internal oracle where the data credit value is stable in correspondence to a FIAT currency within the onocoy system. At swap time, the ONO units are split between a reward pool that incentivizes system contributors and the system treasury that finances maintenance and development of the onocoy system (see Figure 7). Data credits are used to pay for the onocoy service. Data credit value is implicitly tied to FIAT through ONO and the oracle by requiring a variable amount of ONO for data credit depending on the current exchange value of ONO to a FIAT currency. System service costs are denoted in FIAT, enabling customers to predictably know how

Figure 6: onocoy's two-token *deflationary* burn-and-mint model: ONO is utilized in onocoy's governance and incentive design; Data credits are obtained with ONO and provide access to correction data

Figure 7: ONO token flow: ONO are released via halving schedules and lock and vesting contracts; users can acquire ONO to access system services, in turn financing onocoy's operation

much system service they can access with their data credits. This solves the challenge of fluctuating token values often observed in web3 to which traditional and risk-averse stakeholders from the GNSS industry are not accustomed to. Data credits are burned when the service is consumed and are non-transferable. They cannot be swapped back to ONO. Thus, data credits can only be utilized within the onocoy system⁴.

Figure 8 illustrates onocoy's core economy. Miners are owners of CORS that provide GNSS measurements to the system. This data is checked, e.g., on quality, correctness, and continuity, and assigned a quality score by validators. Users can access the GNSS measurement streams via the relay by burning data credits. Users obtain newly created units of data credits by swapping ONO in an on-chain smart contract. A percentage of swapped ONO fills the community fund for system development and maintenance, facilitating economic sustainability of onocoy, a core system value (see Section 3). Another part is awarded to miners and validators as a usage reward for values sharing, another core system value. Yet another part is burned, creating upward price pressure on the token making an investment into and holding of the token rational. Additionally, miners and validators receive newly released ONO tokens as a base reward for network maintenance and roll-out (see Section 3.3 for details).

3.2 Token design

onocoy's deflationary burn-mint token model facilitates stable fiat prices for web3-agnostic customers while retaining the advantages of having its own (value-gaining) blockchain-based token [Kalabić et al., 2023] that can incentivize the setup and maintenance of a global and dense physicial infrastructure network. In particular, onocoy chose 16% for its deflationary factor that has been shown to fulfill these properties.

3.2.1 ONO token

Figure 9 illustrates the ONO token design. The ONO token is a utility token that is used to obtain data credit units which in turn give access to correction data streams (see Section 3.2.2) which, assuming a continuously increasing demand for correction data, is an increasing source of value for ONO (see "Source of Value: Token" in Figure 9). Furthermore, the ONO token facilitates the on-chain governance in the system by enabling ONO token holders to vote on proposals. Assuming that stakeholders have interest in steering the development of the system and its strategy, this provides a further value to the ONO token, as interested parties are required to obtain this token which creates a demand driving up its value (see "Source of value: (Governance) Action" in Figure 9). This upwards price pressure is reinforced by requiring that one lock ONO token units to be eligible for voting on governance proposals. Unlocking ONO from voting is subject to a locking period, thus predictably reducing the amount of ONO in circulation.

⁴Note that, because the data credit is non-transferable and cannot be swapped back to ONO, no third-party market can form on data credits and hence it cannot function as a stable coin.

Figure 8: The core economy of the onocoy system and its supporting smart contracts and tokens

Supply	Capp.	Uncap.			Supply	Capp.	Uncap.		
Transferability	Yes	No	ONC		Transferability	Yes	No		
Burn	Yes	No			Burn	Yes	No		
Fungible	Yes	No			Fungible	Yes	No		
Creation	Action	Consen.	None		Creation	Action	Consen.	None	
Unconditional.	All	Partial	None		Unconditional.	All	Partial	None	
Source of Val.	Action	Consen.	DL	Token	Source of Val.	Action	Consen.	DL	Token

Figure 9: ONO (left) and data credit (right) token design in the categorization scheme of Dobler et al. [2019]

The supply of ONO token units is capped (see "Supply: Capped" in Figure 9). Assuming an increasing demand for correction data over time, keeping ONO supply fixed will create an upward price pressure on it. Finally, a part of the ONO token units that are utilized in swaps for data credits are burned (see "Burn: Yes" in Figure 9), thus continuously reducing the amount of available ONO which creates a further upwards price pressure on the token by reducing its supply.

In order to guarantee incentives for service providers, i.e., miners and validators, and to deploy and maintain a global and dense reference station network, new ONO token units in the onocoy system are continuously released to providers subject to a halving schedule (see "Creation Condition: Action" in Figure 9). In particular, onocoy chose a deflationary factor of 16% per year⁵, which results in a four-year halving schedule of newly created token units until no new tokens come into existence (Figure 7), which is similar to the mechanism applied for block rewards in the Bitcoin system (not accounting for token unit burns). Assuming a 10% discount factor in our calculations, this larger deflationary factor results in a value appreciation of the ONO token [Kalabić et al., 2023] assuming rational actors and a full information scenario (please refer to Section 3.4 for details).

In order to function as a meaningful investment, the ONO token is transferable to enable a cash out by selling token units (see "Transferability: Yes" in Figure 9). This also guarantees that stakeholders are not locked-in to the system. Moreover, the ONO token is fungible to guarantee censorship resistance by preventing the discrimination of specific token units (see "Fungible: Yes" in Figure 9).

 $^{^5\}text{Each}$ year the amount of newly available ONO token units are reduced by 16 %

Figure 10: Miners' rewards in the onocoy network consist of three components that are added together: i) a (possibly boosted) base reward, ii) a usage reward, and iii) a promotional reward.

3.2.2 data credit

Figure 9 illustrates the data credit design. The data credit facilitates the functioning of onocoy's core economy (Figure 8): By burning data credits, users obtain access to RTK correction data streams. Data stream prices are nominated in data credits, which provides value to the token (see "Source of value: Action" in Figure 9). Thus, by retaining data credits, users can predictably know for how long they will be able to access correction data streams. New data credit units come into existence by performing the action of swapping ONO (see "Creation condition: Action" in Figure 9). In order to be accepted by the risk-averse GNSS industry as a payment standard, which requires stable real-world prices of data streams, the data credit value is pegged to a FIAT currency, i.e., the USD, via an oracle. At the time of swapping of ONO to data credit, the current exchange rate of ONO to FIAT is taken into account such that the amount of ONO required for a data credit is inverse to the current FIAT value of ONO. In this way, data credit has a value equal to the utilized FIAT currency *within* the onocoy system. In order for the data credit to **not** be a stable coin, it is non-transferable⁶ (see "Transferability: No" in Figure 9). In particular, data credits cannot be swapped back to ONO. Thus users can utilize the data credit only within the onocoy system for accessing data streams.

In contrast to the ONO token, the data credit supply is uncapped (see "Supply: Uncapped" in Figure 9) to account for a potentially unlimited amount of users accessing an unlimited amount of data streams. In order to function as a unit of account (of potential time to access correction data streams), the data credit is fungible (see "Fungible: Yes" in Figure 9).

3.3 Rewarding concept

Several forms of rewards are provided to contributors of the onocoy system. In this section, we describe the rewards scheme for miners. Other forms of rewards, e.g. a bounty program for bug identification, grant schemes for network development or validator staking for network security and decentralization are discussed and may be introduced in the future.

3.3.1 Miner rewarding

onocoy incentivizes network rollout and maintenance by rewarding data contributors, also referred to as data miners. The amount of received rewards is scaled according to multiple factors such as: i) signal quality, ii) signal diversity, iii) station availability, and iv) location context. Also, special incentives are utilized for early adopters, targeted network expansions and upgrades.

Figure 10 depicts the miner rewards scheme: The *Base Reward* is the reward that miners receive irrespective of the usage of their data and consists of four components:

The *Daily ONO Base Reward*, representing the maximum base reward a miner can earn per day. The value is proposed by the rewards commission⁷ and accepted by the DAO via voting (see Figure 7) and is initially set to reward a well-functioning miner around \$1000 per year⁸, with ONO token valuation provided via oracle, modified with an *Early Mover Boost* that is initially set at 5. Both the Base Reward and the Early Mover Boost are periodically proposed to be updated by the rewards commission, with the intention that the base reward doesn't change too frequently and the boost decrease over time. For the initialization, the choice of Base Reward reflected a fair yearly amortization for a typical reference station and the boost reflected a risk premium for miners that takes into account an already existing base load

⁶If the data credit would be transferable, an external market for data credits could form with potentially another exchange rate between data credit and FIAT then the desired one by the onocoy system. Hence, onocoy would be required to employ mechanisms that would stabilize data credits around the desired exchange, making onocoy a stable coin project.

⁷The rewards commission consists of members of the DAO that are voted in.

⁸Having fiat-fixed rewards for miners has been shown to be required to adequately reward them [Kalabić et al., 2023].

Figure 12: Dilution of the ONO token over time

of reference stations. The *Quality Scale* represents the type and quality of GNSS measurements submitted to the system and is decomposed into "Supported Signals" and "Signal Quality". The *Availability Scale* represents the availability and continuity of the GNSS measurements to the clients/customers (e.g. uptime). The *Location Scale* motivates the optimal distribution of CORS by penalizing overpopulated areas.

The Usage Reward incentivizes sharing the success of the onocoy service within certain regions. The usage reward considers the actual utility (number of data streams in use) and the potential utility (improvement in signal quality) of a particular region which are shared among all miners of a region. Thus, miners of a particular region are incentivized to work together to increase the usage of their data, with the goal of the emergence of a regional community spirit. Furthermore, this incentive is designed as a feedback mechanism for miners to identify valuable spots for reference station deployment such that onocoy results in a self-regulating and self-organizing system [Ballandies, 2023].

The *Promotional Reward* is a bonus incentive administered to miners when the DAO identifies the need for it. This can be a sign-up reward for new miners, e.g., through a partnership program with reference station makers, a dedicated incentive for a quick rollout in a certain area, the promotion of reference stations with certain features such as LEO satellite capabilities, etc..

3.4 Tokenomics

The ONO token is distributed among five stakeholder groups as shown in Table 11. For both founders and investors, tokens are locked for one year and vested for two years afterwards; this reduces downward price pressures on the ONO token via token sales while facilitating a commitment of the founders and investors to the network. In contrast, the team, community, and miners, and validators continuously receive their token units as rewards for their delivered service. Again, the team's tokens are locked and vested, ensuring continued engagement, while the tokens of the other two groups are immediately available, providing a timely return on investment for them. In order to i) encourage network growth in the early days and ii) account for an appreciating value of the ONO token over time. The token units released to the miners, validators and the community are subject to a four-year halving schedule, following recent findings that a deflationary factor is required in burn-and-mint token models to have a stable economy [Kalabić et al., 2023].

This token release schedule manifests into a continuous and decreasing release of tokens over time as depicted in Figure 24.

A rigorous analysis of ONO's value appreciation has been performed in Kalabić et al. [2023] by modeling onocoy's deflationary burn-and-mint token model as a discrete-time, full-information, dynamic game. In this game, all participants are aware of future revenue, so there is no need for speculation and an optimal policy for each participant can be derived. Figure 13 illustrates results from our base scenario assuming a realistic growth in revenues (see the top image in Figure 13) taken from the European Commission report [EUSPA, 2022]. Based on these numbers and the illustrated token dilution schedule (see Figure 24), the circulating token supply (see the middle image in Figure 13) and the value appreciation of the ONO token (see the bottom image in Figure 13) are derived. The result is a lower, i.e., worst-case, bound on the token price since the only factor considered is the value derived from data revenue, as we have not analyzed other positive pressures on the price, such as from governance, or other utilities. Also, novel applications like indoor navigation could be facilitated by the platform that would create a further demand pressure on the ONO token as illustrated in Figure 14, which is not currently considered in the simulation.

Figure 13: Results of our simulation showing expected revenues, token supply and derived value appreciation of the ONO token

3.5 Governance

The purpose of onocoy's governance is to i) enable participation of all stakeholders (incl. users); ii) enable autonomous improvement; and iii) prevent power concentration by any one stakeholder or a group of stakeholders. These elements, in combination, facilitate onocoy's collective intelligence [Ballandies, 2023], which can manage the network successfully in a rapidly changing and complex environment.

To enable all of the above, the governance follows the value of progressive decentralization. In the long run, governance should be decentralized and take place on the blockchain via the ONO token (see Section 3.2.1) as much as reasonably possible: ONO token units provide voting power to the owner of the token – the more tokens one possesses, the larger one's voting power. To prevent power concentration by a stakeholder or a group of stakeholders, two mechanisms are employed: i) anonymous delegated voting with known delegate identities that make concentration of voting power transparent to the community (enabling the initiation of mitigation strategies, e.g., forks) and ii) a modified form of quadratic voting Posner and Weyl [2017], Dimitri [2022], which limits the voting power of larger token stakes by decreasing the marginal gain in voting power of token units for larger stakes (e.g., 1 token unit equals 1 vote, but 4 token units equal 2 votes, 9 tokens – 3, and so on). For the latter, identified delegates are also required to mitigate the risk of Sybil attacks⁹ on voting.

A conceptual schematic of the delegation mechanism is depicted in Figure 15: Community members that are in the possession of ONO tokens anonymously delegate their token units to delegates that have an identity known by the

⁹In the case of quadratic voting, a Sybil attack could be performed by splitting token units to different blockchain addresses/identities controlled by the same stakeholder which would circumvent the quadratic voting.

Figure 14: Over time, novel applications are emerging which create a further upward pressure on the token price, besides the one illustrated in Figure 13.

Figure 15: Delegation mechanism, consisting of community members that delegate (green, dashed line) their voting power to delegates with known identities and who are able to vote on proposals (grey, solid line); all participants have the right to initiate new vote proposals (purple, dotted line).

Figure 16: Legal setup of onocoy's off-chain governance: A decentralized autonomous association governed by ONO token holders which eventually merges the on-chain concept of a DAO with the legal representation of an association.

system. The anonymous delegation facilitates i) a low threshold for participation in the governance and thus enables all stakeholders to participate, and ii) a reasoning in privacy, both required for collective intelligence to emerge [Ballandies, 2023]. The delegates vote on proposals with voting power proportionate to the tokens delegated to them and discounted based on the quadratic voting approach. Note that all community members can submit vote proposals.

The requirements on identity provision for delegates is required in order to identify power concentrations of any stakeholder or group of stakeholders and to prevent Sybil attacks in quadratic voting. Nonetheless, the goal is to formulate requirements such that a large number of community members can become a delegate, thus driving the decentralization of the system.

Initially, the system will utilize majority voting for its decision finding. However, in the future, a different voting mechanism¹⁰ will be employed to improve the alignment of the vote result with community sentiment. This is necessary, as majority voting can result in the "Tyranny of the Majority" [De Tocqueville, 1838]. In general, it has been shown that the type of voting system has a relevant impact on the decision-making process itself, its outcome, and the satisfaction of the community with the result of the process [Helbing et al., 2023].

The governance of the onocoy system is conceptually centered around two funds that contain resources to develop and maintain the system (Figure 5). In the beginning, the off-chain¹¹ FIAT-based investor fund will be considerably larger

¹⁰such as core voting, Borda count or approval voting

¹¹not stored or managed on the blockchain

Figure 17: Off-chain governance of the onocoy system

than the on-chain token-based community fund resulting in a larger importance of the off-chain aspects of the onocoy governance. Nevertheless, over time the value of the community fund will grow, e.g., via token inflow through the swap (see Figure 7) or ONO token value appreciation and thus the on-chain fund will consequently grow in importance. Besides managing the system funds, which consequently steers system maintenance and development, the governance of the system is concerned with setting the system parameters such that they are economically viable and aligned with the community values which prevents system rejection.

Both layers (on-chain and off-chain) are controlled by the same DAO entity that has an on-chain representation in the form of smart contracts and an off-chain representation in the form of a Swiss association. Both representations are controlled by the ONO token via quadratic voting thus merging both of these worlds - virtual and legal - into one via ONO. In order for a token unit to be counted in voting or delegation, the unit has to be locked by the holder. Following the value of progressive decentralization, the overall design goal is to move onto the chain as much of the governance as is legally and practically possible.

In the following, the off-chain and the on-chain aspects are illustrated in greater details.

3.5.1 Off-chain governance

The main purpose of off-chain governance is to comply with external regulations and handle processes and activities that cannot be initially decentralized or governed on-chain *while* following overall governance principles (see Section 3.5). We have therefore chosen to establish onocoy as a non-profit Swiss association, following the best-practice approach of *decentralized autonomous associations* (DAAs) [Ganzoni, 2022]. The association is controlled by ONO token holders and the association owns the intellectual property and system funds, and contracts third parties to develop and maintain the onocoy system (see Figure 16). In particular, ONO token holders control the general meetings of the association via token-based quadratic voting that, among other activities, serves to elect the governance committee, which in turn commissions services to third parties and pays for it via the investor fund (see Figure 17). One of these third parties is the onocoy Services AG in which some of the initial team members have been organized. The goal is to nurture a rich ecosystem of such third-party companies and services. Already, part of the core team is currently made up of several contributors contracted outside of the onocoy Services AG, such as individuals and other companies, whose remuneration in ONO tokens makes them co-owners of the association via their token holdings. In addition, the core team is organized as a Teal¹² organization [Laloux and Wilber, 2014] that is based on, among other things, contributor autonomy and peer relationships, which naturally fits into the governance principles of onocoy in particular and the DAO principles of web3 more generally.

In summary, onocoy has established a Swiss association as a legal entity, used to provide off-chain governance, with the following characteristics:

- It is non-for-profit
- Its purpose is the development, deployment and promotion of the onocoy platform
- It establishes a vibrant ecosystem around the platform
- It can pursue its purpose by performing the necessary task itself or by outsourcing them, e.g., to onocoy Services AG
- It will issue tokens for initial financing and to fund growth

¹²Teal organizations are based on an organizational theory of workers' self-management.

Figure 18: On-chain governance of the onocoy system governed by the GOV DAO and its linking to the off-chain governance via the ONO token

- It may hold interests in additional legal entities
- It is kept as lean as possible
- It adopts supplementary regulations, stipulating
 - Strategic decisions are made on the basis of ONO token shares via quadratic voting
 - That such decisions will be taken on-chain through smart contracts as far as technically and legally possible
 - Election of governance committee and commissions shall be organized on-chain as far as technically and legally possible

3.5.2 On-chain governance

Figure 18 illustrates the on-chain governance of the onocoy system. The supreme on-chain entity is the GOV DAO which controls all on-chain system parts. The DAO is governed by the ONO token (see Section 3.2.1) whose creation mechanism in turn is controlled by the DAO. The DAO governs the utilization of the community fund and configures the multi-signature wallet so that signing entities correspond with the governance committee or commissions of the onocoy association. The multi-sig(nature) wallet has control over the government budget. The multi-sig wallet has the initiative right to request a new government budget from the community fund which has to be approved by the GOV DAO.

The GOV DAO can also set the system parameters of the core economy. Moreover, the GOV DAO decides on the mechanism and trusted addresses of the oracle in the swap mechanism.

3.5.3 Summary: onocoy DAO

The on-chain and off-chain governance of the onocoy system enables the onocoy community to organize itself as a DAO (decentralized autonomous organization).

Our definition of a DAO is informed by the one found in [Ospina and Bohle Carbonell, 2022, van der Molen and Ospina, 2023]. A DAO:

- is decentralized, i.e., has no single source of authority
- is autonomous/ self-sovereign, (individuals are) not bound to an (external) coercive force
- has a shared vision that is (being) worked towards by its members with a shared set of values
- has a shared treasury controlled by a decentralized voting mechanism

The authors van der Molen and Ospina [2023] differentiate between the community and the DAO. The community is made of individuals having relationships with each other and sharing a common identity; the individuals in these communities have different goals, e.g., regarding salary, return on investment, and product design. The DAO is what happens when these actors start to collaborate and align towards a shared vision that satisfies their personal goals.

In an ideal scenario, "a sense of community brings trust and wellbeing which enable better organisation. And effective organisation can enable value flows that sustain community." [Ospina, 2023] In this way, communities and DAOs can form natural symbioses, which result in powerful anti-fragile organizations capable of motivating individuals and communities to accomplish the extraordinary [Ospina, 2023], like setting up global and dense physical infrastructure networks [Jagtap et al., 2021].

With onocoy we are building such a community-powered and community-owned physical infrastructure network for the GNSS industry. In an ideal scenario, this community will organize itself effectively via the onocoy DAO.

Figure 19 illustrates the layers of the instantiated DAO: The center consists of the core team organized as a TEAL organization (see Section 3.5.1) that decides in a decentralized and collective manner on the maintenance, development and growth of the onocoy system, enabled, instantiated and rewarded by the onocoy association which takes decision via the ONO token holders that may or may not be part of the association (see delegated voting in Figure 15). Deliberation and voting are facilitated transparently via on-chain smart contracts and control the association. The core team constitutes and self-organizes itself in competence areas which consists of members with different engagement levels, responsibilities and rights, i.e., the layers in Figure 19. The boundaries between these layers are fluid and permeable. This will empower the self-organization and collective intelligence of the community [Ballandies, 2023] to build the global and dense reference station network.

Figure 19: The membership levels in the onocoy DAO

Figure 20: onocoy's IT infrastructure

4 onocoy's IT infrastructure and validation

onocoy's mission is to develop a dense and globally distributed network of independent miners that delivers low latency and high-quality GNSS measurements to a diverse base of clients via onocoy's decentralized platform. The platform is currently divided into three components: i) a blockchain, which implements the economics and governance presented in Section 3, ii) the validator, which utilizes a variety of GNSS processing techniques to determine the quality of reference data streams (see Section 4.1), and iii) a real time communications network, which connects all components such that low latency of the real-time critical data is ensured. (see Figure 20 for a depiction).

At the time of writing, onocoy's economic component has been deployed via smart contracts on the Solana blockchain, whereas the validator, caster, MQTT communication network and database are still centrally managed by the onocoy association. onocoy's backend is based on a 3 layer architecture:

- Frontend services (NTRIP caster endpoints, console UI)
- MQTT backbone (communication network)
- Backend services (api, validator, database)

To interface both with the external CORS stations and Clients, onocoy uses open industry standards to exchange data (RTCM 3.x and NTRIP 1.0/2.0 HTTP) by implementing the caster functionality. This to maximize compatibility

and realize the objective to become a shared platform for the GNSS industry that is inclusive to all existing and new stakeholders.

onocoy's system architecture is designed with scalability in mind. System critical components can be replicated to accommodate demand and increase redundancy. Multi-region scalability can be achieved by replicating the cluster and bridging the MQTT brokers across geographical regions.

This modular design, using loosely coupled components, enables the system to accommodate changes and updates without significant disruption. It allows for integration of new components or functionalities and enables the system to evolve as needed.

By following the principle of progressive decentralization that facilitates resilience and robustness of the onocoy platform, all of these components will eventually be decentralized. The economic and governance parts will be implemented using smart contracts; the validators may use a proof-of-stake-type algorithm to determine consensus on the quality of data streams, while the caster and MQTT implementation will be expanded with technologies such as p2p gossiping protocols in order to simplify further decentralization of those.

In the following, we present information regarding validator framework (Section 4.1) and the base reward function (Section Section 4.2). Further details regarding decentralization of the caster and communication network and the other types of rewardings in onocoy are forthcoming.

4.1 Validator framework

GNSS measurements submitted by miners are the raw data that a GNSS receiver observes from the signals transmitted by GNSS satellites. These measurements typically contain the time of transmission of the satellite signal and a coarse distance measurement - the pseudorange measurement. Additional measurements captured by the receiver include the carrier-phase and Doppler measurements, where carrier-phase measurements are critical for attaining centimeter-level real-time performance.

The GNSS measurements submitted to onocoy's system are rigorously assessed via the validators to guard against the submission of spoofed and synthetic GNSS measurements. While spoofed GNSS measurements are intentionally deceptive, synthetic GNSS measurements are not typically classified negatively as they provide value-added service in the form of correction data. At onocoy, submission of synthetic GNSS measurements is considered fraudulent as it is seen as an attempt by the miner to emulate authentic GNSS measurements, which leads to undeserved rewards.

In the following, an overview of spoofing and synthetic measurements is presented in Sections 4.1.1 and 4.1.2, respectively. Section 4.1.3 then gives an overview of onocoy's strategy to ensure authentic GNSS measurements are accepted by the platform.

4.1.1 Spoofing

Spoofing refers to the deliberate manipulation or falsification of signals or data in order to deceive or mislead a receiver or system [Jafarnia-Jahromi et al., 2013]. The spoofed GNSS measurements are intentionally generated to deceive a GNSS receiver. Spoofing involves broadcasting fake GNSS signals that mimic accurate GNSS signals but with intentionally modified parameters that cause a receiver to calculate an incorrect position or timing solution [Humphreys et al., 2008].

Spoofing attacks can be carried out using various techniques, such as signal generators, software-defined radios, or replay attacks [Humphreys et al., 2008]. A spoofing attack usually aims to gain unauthorized access to a system or disrupt its operation. Spoofing attacks can have serious consequences, especially in applications that rely on high-precision positioning, such as aviation, maritime, or military applications. Spoofing attacks typically cause receivers to calculate a false position or time, resulting in navigation errors, collisions, or other safety risks. GNSS systems typically use techniques such as encryption, signal authentication, and anti-jamming measures to prevent spoofing attacks Humphreys et al. [2008].

4.1.2 Synthetic measurements

Synthetic GNSS measurements are artificially generated measurements that are not ordinarily intended to deceive a GNSS receiver but provide additional or augmented measurements to complement actual GNSS measurements. Synthetic GNSS measurements can be generated using a variety of methods. However, the most common method is generating correction data for augmentation purposes. One common source of synthetic measurements is from correction service providers that transmit correction data using an Observation Space Representation (OSR). The alternative representation of correction data is using State Space Representation (SSR), where the correction data is

de-correlated into their respective state terms. OSR synthetic measurements are, by design, in a similar format as the GNSS measurements. It is also possible to convert SSR-formatted correction data into an OSR format by transforming the correction data from the state-space domain into the observation-space domain [Seepersad, 2018].

4.1.3 Validating of GNSS measurements

At onocoy, we have deployed a multi-level GNSS measurement processing scheme to guard against the submission of spoofed and synthetic measurements. We examine GNSS measurements over varying time scales using different processing techniques and adjustment methods. We focus on comparing the consistency of the estimated receiver, signal and satellite-dependent state terms across different processing techniques. In Figure 21, we present an overview of the different GNSS measurement processing techniques, which include Single Point Positioning (SPP), differential GNSS (DGNSS) code, Real-Time Kinematic (RTK) and Precise Point Positioning Ambiguity Resolution (PPP-AR). At onocoy, real-time processing is performed using the SPP, DGNSS code and RTK techniques. Daily PPP-AR ensures the miner's location is determined in a global reference frame. More importantly, within the context of fraud detection, PPP-AR ensures global consistency of satellite carrier-phase biases. Post-processed relative baseline solutions are determined against trusted Tier 1 and Tier 2 reference station infrastructure. The varying time scale of the post-processed solution is primarily due to the delayed access of sub-networks of Tier 1 and Tier 2 infrastructure in addition to the utilization of precise orbit and clock products on longer baseline processing. A critical step in our fraud detection is the generation of atmospheric delays and satellite biases from a network solution to ensure consistency amongst a network of miners. Network solutions will be compared against products generated for scientific application to ensure reliability from an independent data source.

Figure 21: GNSS measurement validation framework

As previously mentioned, by design, onocoy opted for an ecosystem that accepted hardware from various GNSS manufacturers as the focus is on developing a community-powered and shared initiative. The GNSS measurement validation framework in Figure 21 has shown high resilience to various attacks examined thus far.

4.2 Measuring the base reward components

Using the validator framework (see Section 4.1), the scales of the miner's base reward are calculated (see Figure 10). The following sub-section details the calculations of the location scale, quality scale, and the availability scale.

4.2.1 Quality scale

The quality scale refers to the supported GNSS measurements submitted by the miner as well as the quality of the measurements. Supported GNSS measurements and the measurement quality are determined by metrics derived from the different GNSS processing methods of Figure 21. Supported GNSS measurements consider the major GNSS (GPS, Galileo, BeiDou and GLONASS) and RNSS (QZSS and IRNSS) constellations. Table 1 presents the reward rate assuming all major GNSS and RNSS were visible. A miner located in Eastern America is expected not to see both QZSS and IRNSS, as such, the reward rate would be updated to exclude these two constellations. GLONASS is given lower importance relative to GPS, Galileo and BeiDou due to the measurement quality of Frequency Division Multiple Access (FDMA) measurements in contrast to the Code Division Multiple Access (CDMA) [J.A Ávila Rodríguez, 2011]¹³. Lower importance is given to QZSS and IRNSS due to their regional coverage.

Constellation	Scale factor		
GPS	0.263		
GAL	0.263		
BDS	0.263		
GLO	0.132		
QZSS	0.039		
IRNSS	0.039		

Table 1: Reward-rate per constellation availability

Each constellation transmits a variety of different frequencies and modulations [J. Sanz Subirana and Hernandez-Pajares, 2011]. Priority is given to the number of available nominal frequencies. Table 2 shows the scale factor with respect to the number of nominal frequency bands that are available.

Frequency Bands	Scale Factor		
L1 or L5 only	0.08		
L1+L2 or L1+L5	0.32		
L1+L2+L5	0.8		
L1+L2+L5+L6	1		

Table 2: Reward-rate per frequency band availability.

To determine the quality of the measurements, a variety of different metrics are utilized. These metrics include cycle-slip-free epochs, GDOP, measurement availability, pseudorange and carrier-range post-fit residuals, solution position error as well as the ambiguity resolution fixing rate. In the near term, the metrics would be expanded to include position repeatability. Table 2 shows the optimal range of values per metric to attain the full-scale factor. These ranges are expected to be further optimized in the near-term to ensure miners are compensated fairly based on the variety of different hardware qualities that are submitted to the onocoy network.

4.2.2 Location scale

Conventional single-frequency RTK performance is limited to baselines of less than 15km, as longer baselines may not effectively account for errors within the GNSS measurement. The objective of relative positioning is to reduce or eliminate error sources by mathematically differencing simultaneous GNSS measurements from multiple receivers. Accuracy in conventional single-frequency RTK is correlated with baseline length and amounts to approximately 0.1 to

¹³Note that onocoy anticipates equal rewards for GLONASS once its modernization efforts attain operational status.

Measurement quality performance metric	Optimal conditions to earn full reward		
cycle-slip-free epochs	> 80%		
measurement availability	> 60%		
pseudorange post-fit residuals (rms error)	< 0.5 m		
carrier-range post-fit residuals (rms error)	< 0.02 m		
solution position error	< 1 cm horizontal and < 3 cm vertical		
ambiguity resolution fixing rate	> 80%		
GDOP	< 5		

Table 3: Optimal conditions to earn full measurement scale factor

1 ppm for baselines up to some 100km and then less for longer baselines [Euler and Schaffrin, 1991]. In Seepersad et al. [2015], baselines were extended up to 50 km under optimal ionospheric conditions, and altitude differences were limited to 400 m due to differences in tropospheric effects. These findings, which are well documented in the literature [Tobias et al., 2011, Rothacher, 2002, Euler and Schaffrin, 1991], highlight two important factors in the spatial distribution of miners which include sensitivity to varying baseline lengths in 1) the horizontal component, and 2) elevation difference.

The goal of the location scale is to

- incentivize spatial distribution of infrastructure
- · ensure necessary infrastructure redundancy
- encourage the installation of higher-quality miner infrastructure in areas with low-quality miners (in availability and signal quality)

The current version of the location scale issues a penalty to miners within a defined radius of each other (initially set to 70km). To allow infrastructure redundancy, nearest neighbours are excluded from the calculations. The amount of nearest neighbours which are excluded will be revised regularly and depends on the evolution of the network. A full penalty is applied to non-excluded neighbours within a close radius (initially 20km) as no additional information is gained once we have established the necessary infrastructure redundancy. To minimize clustering during the rollout of the network, a less stringent penalty is applied to those > 20 km and < 70 km.

The implementation is performed as follows.

- 1. An inner and an outer radius for distances is defined based on the 3D distance, where the inner reward radius is 20 km and the outer reward radius is set to 70 km.
- 2. For each base station, all nearby base stations are listed ordered by distance ascending where distance represents the 3D baseline distance between the current station and the neighbouring station. The current station has an index equal to 0 and neighbouring stations range from 1 to N where N is the total number of stations within the outer radius.
- 3. The first X neighbours are ignored from further calculations, where X is the designated infrastructure redundancy value.
- 4. The distance penalty for miners within the search area is determined, where the distance penalty is a value between 1 (full penalty) and 0 (no penalty). If the distance is less than the inner radius, the distance penalty will be set to 1. Furthermore, the distance penalty will linearly decrease from 1 to 0 relative to distances between the inner and outer radius.
- 5. The distance penalty based on a shared factor is determined, where the shared factor is defined as the ratio of the grades (quality and availablity) of both stations. The shared factor is a value linear between 0 (no rewards) and 1 (full rewards).
- 6. The location scale is determined by multiplying all reduction factors.

4.2.3 Availability scale

The availablity scale represents the completeness of a data stream during a given time period. Next to the connection duration, also measurement availablity is monitored, as a RTCM station is expected to send a full data set every

id	dist. (km)	sig. rew.	dist. penal.	share factor	reduct. factor	
0	0	0.5	-	-		
1	5	0.1	-	-	-	
2	18	0.5	1	$\begin{array}{c} 0.5 = \\ \frac{0.5}{0.5 + 0.5} \end{array}$	$0.5 = 1 - 1 \times 0.5$	
3	30	0.25	$0.8 = 1 - \frac{10}{50}$	$\begin{array}{c} 0.33 = \\ \underline{0.25} \\ 0.5 + 0.25 \end{array}$	$0.73 = 1 - 0.8 \times 0.33$	
4	60	1	$0.2 = 1 - \frac{40}{50}$	$0.67 = \frac{1}{0.5+1}$	0.86 = 1-0.2 × 0.67	
Location scale for miner 0 is $0.3139 = 0.5 \times 0.73 \times 0.86$						

Figure 22: Illustration of location scale calculation parameters utilized in Table 23: red bottom number - station index of miner; black top number - signal quality scale of miner; blue circle - inner reward circle; orange circle outer reward circle.

Figure 23: The location scale for a target miner is calculated by multiplying the reduction factors of all miners within the outer reward circle (70 km radius) around the target miner. This sample calculation is for miner 0 in Figure 22. Using a redundancy of 1, the miner with index 1 is excluded from the calculation.

epoch/second. A dynamic system grant is added to the measured availability to cope with potential system/network errors. The value of a station regarding its availability is not a linear function as a continuous stream is key for the data consumers. Therefore data availability below a threshold (initially 80%) is set to a scale of 0, and an exponential function (initially quadratic) is used to model the availability scale between measured data availability between 80% and 100%.

5 Call for action

onocoy is on a mission to provide a dense, high-quality GNSS reference station network to unlock the enormous potential of high-precision positioning all accross the globe. To do so, it relies on cutting-edge web3 concepts including smart contracts, decentralized ownership, community participation, and blockchain technologies.

onocoy's unique approach decouples GNSS reference station infrastructure management from correction service provision. Token-based incentives and the systematic use of open standards allows onocoy to tap into the existing installed base of mass market GNSS reference stations and, when required, bring about targeted infrastructure development, quickly and efficiently closing gaps in geographical coverage and technological capabilities. onocoy is the most efficient way to solve the ecosystem problem of creating a global and dense GNSS reference station network.

Our vision is to build this network as a community-owned, decentralized, and transparent system to ensure inclusive, discrimination-free access to and use of GNSS high-precision technology across all borders.

To achieve this ambitious goal, we require the skills, contributions and visions of each and every one of you – GNSS experts and enthusiasts, web3 hodlers and builders, IT specialists and hackers, ROI miners and idealists –

We require you.

Join us.

We are on a mission.

Figure 24: Let's unite – for a future that brings high-precision positioning to earth and beyond.
